ABSTRACT

Increasing attention has been paid to regional innovation systems. However, previous studies have so far only focused on (the regional impact of) national policies or specific regions. Despite increasing attention to regional and local innovation policies, no studies have been carried out to date on the factors of implementation and design of local research and development (R&D) subsidy programs at the city level. Our research fills this gap by using information on R&D subsidy programs from local authorities in Japan collected via websites and our original survey. Thus, our research aims at empirically investigating the determinants of both implementation and design of local R&D subsidy programs at the city level (length and upper limit of subsidies, and flexibility of subsidy conditions) considering both demand- and supply-side factors. We employ probit models for basic empirical estimations and provide some robustness checks. The empirical results suggest that, after controlling for city type and population size, supply-side factors including local government conditions significantly affect the implementation of public R&D subsidy programs. In contrast, we find that demand-side factors matter more for the design of subsidy programs than supply-side factors.

1. INTRODUCTION

Generating innovation and new business through R&D is important from the viewpoint of promotion of the regional economy. Accordingly regional innovation systems have attracted much attention both from academia and practitioners (Cooke2001). Whereas firms universities and regional governments ought to play important roles in the conceptualization of regional innovation systems (Leydesdorff and Etzkowitz1996) there is not sufficient empirical evidence on the role of local governments in the discussion of regional innovation systems. On the one hand, while the central government is expected to plan national policies considering the general welfare of the nation local authorities play a complementary role as they are often required to implement these national policies for local parties. On the other hand, they are also expected to develop original policies that may be better suited to local conditions and needs (Perry and May2007). We may therefore expect to encounter a large variety of local policies according to different conditions of local authorities and different needs of local firms.

To date, there have been numerous studies on the central government's innovation policies including the promotion of regional clusters (Martin et al.2011;Nishimura and Okamuro2011a;Töpfer et al.2019). In addition several studies targeted specific regional policies and provided detailed case studies on these policies (Bellucci et al.2019;Sharif and Xing2019;Morisson and Doussineau 2019). However, despite increasing attention to local policy initiatives, econometric studies on the determinants of implementing local government policies, especially city level innovation policies, are scarce. Regarding environmental sustainability policies, some empirical studies examine the determinants of such policies at city and county levels in the USA, focusing on political factors (Hawkins et al.2016;Laurian et al.2017). However, no studies analyze the determinants of regional innovation

policies except for a study of state-level Small Business Innovation Research (SBIR) program (Lanahan and Feldman2015). Moreover, no studies address the determinants of program designs. Hence, our research aims are to empirically investigate the determinants of both implementation and design of R&D subsidy programs by city governments using unique Japanese data.

In Japan, with a traditional centralization of policy-making, national government has always played a major role in promoting regional economies. Even though the promotion of regional innovation has been recognized as an essential policy issue since the beginning of this century under the “Science and Technology Basic Plan” it was the Ministries of Economy Trade and Industry (METI) and of Education Culture, Sport Science and Technology (MEXT) that took the initiative in cluster policies (See(Kitagawa2007;Okamuro and Nishimura2018) for these innovation policies). However in 2014 the Japanese government initiated the “Chiho Sosei” (regional revitalization) policy encouraging local authorities to plan and design their own “General Regional Strategy” considering regional economic conditions and development trends. An important background of this new policy is the decline of the Japanese population especially in rural areas due to rapid aging and low fertility rate. This new policy trend gives local governments a new more important position in regional revitalization, although policy initiatives may differ significantly according to local needs and conditions. This is the major reason for our research focus on local authorities especially city governments.

Also in Europe, multilevel policy mix including both EU and regional innovation support policies has already been implemented. Fitjar et al.(2019) suggest that, in 2011, the EU Directorate-General for the Regional and Urban Policy (DG Regio) introduced the Research and Innovation Strategies for Smart Specialization (RIS3), “a place-based policy which foregrounds the role of regions and emphasizes research and innovation policy, building competitive advantage based on regional strength and potentials” (p. 1). In the period 2014–2020, EU regions were required to develop their own smart specialization strategies as a condition for access to European Structural and Investment Funds. In European studies, however, regional policies are not clearly distinguished from municipality policies, so that municipality policies may be still negligible. In this sense, recent innovation policy in Japan involving and encouraging city governments is distinctly unique worldwide and worth researching.

It is well known that the structure of public expenditures (the balance between different purposes) varies across local governments. Previous studies in public policy research find that the balance of expenditures depends on economic and institutional constraints, political imperatives, and actual needs (Hajnal and Trounstone2010). In fact, for a direct and concrete policy targeting local firms, such as an R&D subsidy program, our original survey data found a large variety of program designs among cities regarding volume, conditions, and selection procedures. For example, the upper limit of subsidy per project varies from less than one million to 50 million yen with a median of two million yen. Subsidy ratio to total project budget varies from 20% to 100% with a median of 50%. Regarding the flexibility of R&D expenses, only 34% of local governments allow public subsidies to be spent on personnel expenses. Thirty percent allow recipients to obtain other public subsidies for the same project. Before estimating the effects of public support with respect to program design, it is important to examine whether such variety is random, and if not, what determines such variations. However, to the best of our knowledge, no previous studies have empirically addressed the determinants of policy design.

Our research will fill this gap by targeting the variety of local innovation policies at the city level in Japan. Thus, our research aims are to empirically investigate the determinants of both implementation and design of R&D subsidy programs by city governments using unique Japanese data. Based on website information of local authorities in the entire country and using original and unique survey data for public officers responsible for local authority R&D subsidy programs, we explore the variety of regional innovation policies. Next, we investigate the determinants local R&D subsidy program implementation and their design at the city level using multiple regression analysis. As Tödtling and Trippel(2005) argue, no innovation policy can fit all regions because of a wide variety of regional characteristics. Rather, it is important to consider regional variety in the implementation and design of innovation policies by local authorities.

The remainder of this paper is organized as follows: In Section2, we provide a brief review of the related literature. In Section3, we describe the process of the R&D project by local firms and its relationship with local R&D subsidy program. In Section4, we provide theoretical background and hypotheses. In Section5, we explain our sample and data from our original survey for empirical estimations. In Section6, we elaborate estimation models and report the empirical results. In Section7, we conclude this paper by presenting some future research agendas.

2. LITERATURE REVIEW

Regional innovation systems comprising local Small and Medium Enterprises (SMEs) research institutes and local authorities have attracted increasing attention since the seminal works by Cooke et al.(1997) and Cooke(2001) whereas there have been few studies on the innovation policies of local authorities. A special issue

in Regional Studies focused on the multilevel governance of science (and innovation) policy and provided a comparison of the changing balance between central government and regional governments towards greater decentralization by contrasting centralized countries (England, France, Finland, and Japan) with federal countries (Germany and Canada) (Perry and May2007). The articles in this special issue provide descriptive studies of science policy in each country with program-level (Salazar and Holbrook(2007) for Canada) or regional case studies (Crespy et al.(2007) for France Sotara and Kautonen(2007) for Finland Koschatzky and Kroll(2007) for Germany) and historical review (Perry(2007) for England Kitagawa(2007) for Japan). It is also noteworthy that they all target regions or states instead of cities or counties².

An OECD report addresses the multilevel governance of innovation policies at different administrative levels (sub-national, national, and supra-national) and refers to some different patterns of governance among member and non-member countries (OECD2011). There are some conceptual papers on the multilevel policy mix on innovation (Flanagan et al.2011;Laranja et al.2008), while Fernandez-Ribas(2009) compares the effects of innovation programs in EU regions between different levels of governments (regional, national, and EU levels), without considering municipality or city level.

More recent literature of science policy suggests that the decentralization of science and innovation policy has been promoted in the last decade. In the EU, the Directorate-General for Regional and Urban Policy (DG Regio) implemented in 2010 the Research and Innovation Strategies for Smart Specialization (RIS3).In the program period 2014–2020 regions are requested to develop their own strategies as a condition for access to European Structural and Investment Funds (Fitjar et al.2019). In Norway, a non-EU country, nineteen country governments were given responsibility for one percent of the nation’s total publicly funded research by the central government decision in 2010. These country governments were then required to develop their own R&D strategies and to cooperate with each other through new institutional arrangements (Kolltveit and Askim2017).

Several previous studies focus on the impact of national cluster policies. Specifically some empirically investigate local effects of national cluster policies in France (Martin et al.2011;Fontagn é et al.2013) and Germany (Engel et al.2013;Töpfer et al.2019) at firm and local levels. For Japan, Nishimura and Okamuro(2011a,2011b,2016) and Okubo et al.(2016) empirically examine the effects of METI’s cluster policy at the firm level. Using a unique micro dataset Okamuro and Nishimura (2018) provide a comparative econometric analysis of the project-level effects of METI’s and MEXT’s cluster policies that have similar aims but contrasting schemes. However they do not consider the role of regional or local governments³.

In addition, several studies targeted specific regional innovation policies and provided detailed case studies on these policies (Bellucci et al.2019;Morisson and Doussineau2019;Sharif and Xing 2019). However, despite increasing attention to local policy initiatives, econometric studies on the determinants of implementing local government policies, especially city level innovation policies, are scarce.

Since the seminal papers by Leydesdor ff and Etzkowitz(1996) and Etzkowitz and Leydesdor ff (2000), the concept of Triple Helix has paid attention to the coordinator roles of national and regional governments in university–industry–government collaboration. However, most studies in this line provide conceptual discussion and case studies of specific industries or nations. Empirical studies targeting city government’s roles are scarce.

A special issue in the journal *Technological Forecasting and Social Change* in 2019 (Appio et al. 2019) provides a systematic assessment and integrative view of the “Smart City” policy that recently attracted worldwide attention. The purpose of this policy is “to increase the competitiveness of local communities through innovation while increasing the quality of life for its citizens through better public services and a cleaner environment” (Appio et al.2019, p. 1). In this special issue Caragliu and Bo(2019) find positive impact of this policy on urban innovation (measured by patenting) using a panel data set of 309 European metropolitan areas and Propensity Score Matching. However, they neither consider the determinants of nor the variety in these policies.

Why is it so important to consider the city level policy initiatives? A recent empirical study from Japan confirms that multilevel R&D support is highly effective on the recipient’s productivity, especially when it includes city level support (Okamuro and Nishimura2020), although city level programs usually aim at small and no high-tech innovation. Their finding is consistent with the argument for the decentralization of policy-making that “activating regional R&D potentials can be difficult if science policy governance is highly centralized” (Kolltveit and Askim2017).

In other policy fields in which local initiatives and multi-level governance are considered to be essential, some empirical studies have been conducted at various levels of local government. For example, local governments are increasingly involved recently in the development of environmental sustainability policies. Accordingly, a couple of empirical studies investigate the determinants of implementation of such policies at city and county levels in the USA, focusing on political factors (Hawkins et al.2016;Laurian and Crawford2016;Laurian et al.2017). More generally Foucault et al.(2008), using a dynamic panel data model of French municipalities, examine interactions between neighboring municipalities regarding primary and

investment expenditures Hajnal and Trounstein (2010) analyze the effects of economic and institutional constraints, political imperatives, and actual needs on the balance between redistributive allocational and developmental spending in the USA at city and county levels.

However, apart from a few recent studies (Lanahan and Feldman 2015; Lanahan 2016) that target state-level small business innovation research (SBIR) programs in the USA, to the best of our knowledge no empirical studies have so far been carried out on the determinants or effects of regional innovation policies by local authorities with respect to their variety. The 2015 study by Lanahan and Feldman explores the determinants of additional financial support by the states for the recipients of federal SBIR programs, while the latter by Lanahan (2016) examines the effects of additional state support for SBIR recipients. Lanahan and Feldman (2015) use a panel dataset of all states in the USA for the years 1983–2010. They argue that top–down (national policy variables), lateral (neighbor states' policy), and bottom–up (political and scientific environment of the state) factors incur the implementation of additional state-level support for the federal policy and find that most of these variables significantly affect the propensity of state SBIR. However, they do not target any local authorities lower than state-level, nor do they address any variations across state SBIR programs.

This paper will fill this gap by empirically investigating the determinants of both implementation and design of city-level R&D support policies in Japan using original survey data. Focusing on city-level innovation policies which are independent of national policies, is especially important because they lack empirical investigation and evidence despite recent transformation of local governments' roles from passive (regions as stages and implementers) to active (regions as partners and independent policy-makers) (Perry and May 2007) which is striking in the case of Japan. This paper is original in that it targets not only the implementation but also the variety in the design of R&D support policies by local authorities in Japan especially in cities, where authorities are smaller and have less administrative power and responsibility than those in federal country states. Due to the cross-section nature of our dataset we focus on the bottom–up factors used by Lanahan and Feldman (2015) which we reorganize into demand and supply factors.

3. PROCESS OF LOCAL R&D SUPPORT PROGRAMS AND R&D PROJECTS

In this section, we describe the whole process of the local R&D subsidy program in relation to local R&D projects in order to illustrate how R&D support programs of local governments are managed, interacting with local R&D projects. The description in this section is based on the authors' own survey and hearing information from the program officers of city governments. We found a large variety of support programs across cities and local governments, but show just an average pattern of program implementation. Based on the description, we can argue how program design, especially the term and ratio of subsidy to total project budget and the flexibility in project management (the dependent variables of our estimations), is important for the innovation by recipient firms and projects.

(1) Call for applications: R&D subsidy programs by city governments mostly depend on their own annual budget (sometimes supported by central government's fund). For two-thirds (67%) of the respondents (city programs), the support is limited within one year (by the end of the same fiscal year). For the rest of the programs, public support is usually renewed every year after submitting project report. Since the fiscal year starts in April in Japan, call for applications of most programs are announced in April or later. The selection starts after the application deadline in May, June, or July. Since the recipients have to accomplish their projects and present project report by February or March in the following year, the real project term is limited to at most nine months. Call for applications is announced on the city government's website and through the local chambers of industry and commerce and industry associations to potential applicants. Due to short terms, the applicants often organize and start R&D projects before they submit project proposals.

(2) Selection procedure: Due to a limited program budget (on average 18 million yen on average in 2015, but the median is six million yen), there is often a competitive selection of recipients. Around 71% of the programs organize an evaluation committee, which has 5.8 members on average. Most of the juries are experts from outside the city government, such as local university professors and board members of local chambers of industry and commerce. In 2015, on average, each program received 6.1 applications (median is four), among which 4.6 (median is three) projects were accepted for subsidy. Project evaluation is often (85%) made through application documents and interviews. About 10% of the programs got no applications in 2015. The ratio of acceptance was 85% on average.

(3) R&D project implementation: The upper limit of the R&D subsidy significantly differs across programs, but its mean is 3.7 million yen (median 2.0 million yen). Usually R&D project can only partially be supported, and the rest should be self-financed. For half of the programs (51%), the subsidy ratio is up to 50% of the total project budget. Each accepted project received 2.4 million yen on average in 2015 (median 1.3 million yen), but the recipients have to conduct the R&D projects with their own funding. In almost one-third of the cases (36%) the recipients are officially allowed to request partial advance payment of R&D expenditures, but

usually they do not receive advance payment, but reimbursement of their R&D expenditures after they accomplished the R&D project and submitted the project report. Moreover, in two-thirds of the programs (66%), it is not allowed to expend the subsidy for personnel costs. For several city programs (46%), the recipients can obtain technological and managerial support for their projects through the city government. As the small amount and short term of the subsidy suggest, city R&D support programs usually promote small, no high-tech, and development-oriented innovation rather than high-tech and science-based R&D.

(4) Project report/evaluation and subsidy grant: In two-thirds (65%) of the programs, the accepted projects are subject to mid-term evaluation (even for a short-term project within one year). Formally, the city government can discontinue a project or reduce the subsidy amount depending on the mid-term evaluation in many cases (73%). After the subsidy period, all programs require final reports about project outcomes, such as new product prototypes, from the recipients. In some cases (39%), an additional interview (oral presentation) is requested for final evaluation. Formally, in several programs (66%), the city government can reduce or even disapprove the subsidy depending on the final evaluation.

(5) Follow-up: After the support program finishes, program officers often (in 55% of the programs) follow up with the recipient projects for three to five years to check the development of outcomes. Sometimes the recipients are invited by program officers to other related programs of the same city government or prefecture/national support programs.

It is noteworthy that, although a minority (24%) of the programs is designed considering the relationship with prefecture and national R&D support policies, two-thirds of the programs (67%) prohibit multiple subsidization of the same project by prefecture or national programs. According to our interviews with city program officers, the reasons for this restriction are to avoid the concentration of public subsidies on a few projects and to secure diversity in public support. As mentioned above, city government programs usually support small nonhigh-tech projects of small local firms that aim at relatively simple development of new products within one year.

4. THEORETICAL BACKGROUNDS AND HYPOTHESES

As previously mentioned, with a traditional centralization of policy-making, central government in Japan always played a major role in promoting regional economies. Even though the promotion of regional innovation has been recognized as an essential policy issue since the beginning of this century, METI and MEXT adopted the initiatives of cluster policies. Local authorities have been gradually acknowledged as partners in cluster policy, but it was not until the introduction of the Regional Revitalization Policy (Chiho Sosei) in 2014, that local authorities were encouraged and competitively supported by the central government to plan and design their own development policies with respect to local economic conditions. With this new national policy trend, local governments obtain a new and more important position in regional development.

Perry and May(2007) provide a conceptual framework for the “regional dimension” to science policy. Regions may play passive roles as stages and implementers of national policies and active roles as partners of central government and independent policy-makers. Recent developments in Japan demonstrate that Japanese local authorities (prefectures and cities) are changing rapidly and increasingly from passive to active players with the pressure and support of national policy. However, the extent of such a transformation may vary significantly across local governments Perry and May(2007) explain the role of regions as independent policy-makers as follows. “Regional authorities and bodies are increasingly devoting their own finance and resources to funding regionally significant scientific investments or projects. The emergence of ‘regional science policies’ may be characterized by independent agenda-setting, institutional creation and new governance arrangements, new mechanisms and policy tools or strategic intelligence and capacity building” (p. 1042). Local authorities may differ regarding their motivation, resources, and capability.

Local government policy decisions are not random, but may be influenced by different factors. As we reported in the previous section, we found at least two empirical studies using US regional data that consider the factors for decision-making by local governments from multiple perspectives. In this section, we first explain the empirical models in these studies in more detail in order to derive our own theoretical basis for the hypotheses, considering the specific Japanese context.

Hajnal and Trounstone(2010) consider four factors for the balance of public expenditures: economic, political, and institutional factors, as well as actual needs or local context, and found that each of these factors is important. To elaborate, economic factors include the economic resources of and competition between local governments, for which they use government revenue per capita and the central city dummy as proxies. The political factor refers to local public preference which is represented by share of votes for the Democratic candidate in presidential elections. Institutional factors cover local, state, and federal institutions, among which

differences in local administration patterns are regarded as especially important. Actual needs (local context) are measured by regional dummies, poverty rate, unemployment rate, and population size.

By focusing on local R&D subsidy programs, which are not essential for local governments, we can more clearly address local economic conditions and distinguish between supply- and demand-side factors than previous studies Lanahan and Feldman(2015), who estimate fixed effect models using US state data for 28 years, consider top-down, lateral, and bottom-up factors. Top-down factors (time-series variation in the national policy) consist of the variables of federal R&D funding and industrial specialization in public procurement. Lateral factors reflect policy imitation or bandwagon effects, which are measured as the proportion of neighboring states with policy implementation. Bottom-up factors (regional conditions) are the Democratic governor dummy, its interactive term with early scientific advisory system, fiscal health (state revenue), and the variables of high-tech employment and higher education capacity.

We are more interested in the effects of local (cross-section) variations than time-series variations on public subsidy. Local R&D subsidies at city level are relatively new policy programs in Japan, where most programs have traditionally been centralized and, until recently, there has been very little room for local policy initiatives. In this context, top-down or institutional factors have little importance compared to the US, where institutions and laws differ significantly across federal states. Moreover, in the context of Japanese policy, competition between two major political parties has not functioned well. Most mayors are either “conservative” or “independent,” but seldom belong to the opposition party in the central government, in which the conservative Liberal Democratic Party has almost always been the ruling party. Therefore, we concentrate on economic factors and actual needs (Hajnal and Trounstine2010) and in particular, bottom-up factors (Lanahan and Feldman2015), which we reorganize into demand- and supply-side factors.

Public expenditures by local governments depend on their revenues, which are mainly based on tax and public debt. Therefore, local governments can be viewed as being under fiscal constraints and they should consider fiscal health (McDonald2018). In light of these constraints, different policy schemes compete for limited budgets, and since it is often difficult to avoid or decrease the expenses of existing policies, launching a new policy program, especially a subsidy program, is a challenge for local governments. Therefore, local government’s revenue is an important factor for R&D subsidy (Lanahan and Feldman2015). Moreover, administrative capabilities regarding R&D support programs may differ significantly across local authorities due to the quantity and quality of available human resources (Charron et al.2014;Morisson and Doussineau2019). Indeed, using American municipality data Hajnal and Trounstine(2010) argue and find that both economic and political constraints affect local government’s decisions on public expenditures. Therefore, we argue that the implementation of local R&D support programs depends on supply-side factors including fiscal constraints and the administrative capability of local authorities. Thus, we propose the following hypotheses on the effects of supply-side factors:

Hypothesis 1a: Local authorities that are financially less constrained and that provide more administrative services, especially for local firms, are more likely to implement R&D subsidy program.

Hypothesis 1b: Local authorities that are financially less constrained and that provide more administrative services, especially for local firms, are more likely to design R&D subsidy program in a more favorable way for potential recipients.

Regarding demand-side factors, actual policy needs of local firms are also important, as argued by Hajnal and Trounstine(2010). Here, we argue that not only actual needs, but also potential needs are important (Morisson and Doussineau2019). Therefore, the larger the potential local needs for such programs, the more likely local authorities are to implement them. Although it can be also argued that local authorities of regions that lag behind in R&D activities are more eager to catch up with subsidies to local firms, asLanahan and Feldman(2015) point out, we argue that efficient policy measures should consider local needs. Therefore, we propose the following hypotheses on the effect of demand-side factors:

Hypothesis 2a: Local authorities of regions with higher research potential of local SMEs are more likely to provide R&D subsidy programs in response to higher demand by local firms.

Hypothesis 2b: Local authorities of regions with higher research potential of local SMEs are more likely to design R&D subsidy programs in a more favorable way for potential recipients in response to higher demand by local firms.

Regarding R&D subsidies for local firms, local needs may be specific in the sense that not every local firm is eligible for the subsidy. It is well known that R&D is concentrated in the manufacturing sector, and more so in some industries within the manufacturing sector. Therefore agglomeration of manufacturing firms and specifically high-tech firms in R&D intensive industries, are important demand measures. When considering the competition between different policy purposes, we argue that the share of potential firms with R&D investment in each city is an appropriate variable for the demand for R&D subsidy, when controlled for economic size

(population size) of the city. Moreover, we propose using average labor productivity of local manufacturing firms as a proxy for potential innovativeness of local firms⁴.

Moreover, the national government promotes collaborative R&D with other firms, universities, or public research institutes through the allocation of specific subsidies (Nishimura and Okamuro 2011b). Triple Helix theory argues that governments play coordinator roles in promoting university–industry–government collaboration (Etzkowitz and Leydesdorff 2000). Accordingly, most local R&D support programs target collaborative R&D projects, as we show later in the data section. Therefore, the availability of potential R&D partners in the region including universities and public research institutes may be an essential element of the implementation of local R&D subsidy programs. Hence, we propose the following hypotheses on further effects of demand-side factors:

Hypothesis 3a: Local authorities of regions with more potential R&D partners (including universities and public research institutes) are more likely to implement subsidy programs in response to higher demand.

Hypothesis 3b: Local authorities of regions with more potential R&D partners (including universities and public research institutes) are more likely to design subsidy programs in a more favorable way for potential recipients in response to higher demand.

We propose the above hypotheses regarding the effects of supply- and demand-side factors both on the implementation and design of local R&D subsidy programs. Basically we consider that the same factors of program implementation apply to program design, thus both supply- and demand-side factors affect program implementation as well as program design. Yet as the capacity of supply is the first and major hurdle of public policy, supply-side factors like fiscal constraints and administrative capability may be considered to be more important than local needs for implementing such programs. However, once the local authorities decide to implement their own R&D subsidy programs, they will also consider local needs as far as possible when designing their programs according to the program goals. Therefore as a whole supply-side factors of local authorities may be more important for implementing R&D subsidy programs than demand-side factors, and demand-side factors are more important in designing these programs. We will compare the effects of supply- and demand-side factors in our empirical estimations.

5. SAMPLE AND DATA

This paper aims at empirical (thus econometric) estimations of the determinants of both implementation and design of local R&D subsidy programs at the city level. Specifically, we consider both demand- and supply-side factors and compare their effects (we explain the estimation models in detail in the following section). For the first purpose, to investigate the determinants of program implementation, our sample should cover all cities in Japan, while we need information about which cities implement their own R&D subsidy programs. For the second purpose, to investigate the determinants of program designs, we target the cities with R&D subsidy programs, for which we need detailed information about program designs.

The sample for the first estimation covers all 813 cities in Japan (including special wards in Tokyo)⁵. We checked the website of each city in Japan in 2015 to derive some basic information about public R&D subsidy programs for local SMEs and start-ups, which local authorities (city governments) implemented for the fiscal year 2015. The target projects of these programs include single firm projects, inter-firm collaboration, and university–industry collaboration. We exclude those support programs that ended before 2014 and those in which the maximum amount of subsidy per project is under one million yen in order to select active programs with a substantial amount of subsidy per project. Finally, we confirmed 179 local R&D subsidy programs in 154 cities among 813 cities (18.9%) as of 2015.

Then, we collected local and administrative data of each city from various public sources including the Economic Census (Statistics Bureau) and the Census of Manufacture (METI), and public information about city governments. Eventually, our sample was reduced to 772 cities due to missing data for administrative mergers. Among these 772 cities, 129 cities (16.7%) implemented R&D subsidy programs as of 2015.

Then, we conducted an original online survey of relevant city government officers on the content and strategy of these programs⁶. Questionnaire items include (1) program contents (start year, targets and conditions, limit and ratio of subsidies, program budget and expenditure, number of applications, and selected projects); (2) procedures of selection and evaluation (selection method, support for selected projects, progress check, project report, and final inspection); and (3) background of program designs (relatedness to national policy, past programs, self-evaluation, factors for subsidy criteria, and future agenda). After a pre-test with two programs, questionnaires were sent to the relevant government officers of 177 local programs in January 2016. We obtained responses on 151 programs in 131 cities (response rate: 85.3%)⁷. Among them, we did not use two cities for missing data, so the sample size was reduced to 129 cities (16.7% of 772 cities). The second estimation on

program designs focuses on at most 120 cities among them, since some cities had to be omitted due to missing local data.

In the following part, we briefly describe our survey results focusing on 151 programs in 131 cities. The description of program design partially overlaps with that in Section 3. The earliest local policies date back to the 1980s, but the median year of the implementation of the current policy program is 2009, which suggests that most local administration began their own R&D support programs relatively recently. Although there are few R&D subsidy programs that support only single-firm projects (11%), most programs also target single-firm projects. Half of the programs include university–industry collaboration in their targets. Most programs (88%) support only local firms in their own region, but in most programs project partners can be located elsewhere.

Subsidy duration is generally short: Two-thirds (67%) are limited to within one year. The average subsidy ratio to total R&D expenses is 58% (median: 50%). Most programs request partial self-payment of R&D expenditures by subsidy recipients, which may restrain their moral hazard. The average ceiling on R&D subsidy per project is 3.66 million yen (median: two million yen). Personnel expenses are allowed in one-third of the programs (34%), as is the advance payment of the subsidy (36%). The program budget in the fiscal year 2015 is on average 18 million yen (median six million yen) while the actual expenditure is on average 9.6 million yen (median four million yen in median).

Finally, regarding the relatedness to national programs, 67% of city programs do not support projects subsidized by prefecture or national programs in the same year. Thus, city programs are often designed as substitution for prefecture or national ones. The amount and conditions of subsidy are determined considering those of prefecture or national programs in 24% of the cases, while 27% of the programs create rules based on the situation of local firms.

6. EMPIRICAL ESTIMATIONS ON LOCAL R&D SUBSIDY PROGRAMS

6.1. Estimation Models

We explain the empirical models to estimate the local authority's propensity to implement its own R&D subsidy program and the determinants of the designs of these programs. We employ a probit model for both estimations because all dependent variables are dummy variables.

In the first estimation, the dependent variable is the dummy variable that takes one if a city implements its own R&D support policy in 2015 and zero otherwise. Almost 17 percent of the 772 cities in the sample (129 cities) implemented their own R&D subsidy program in 2015. We use the following city-level independent variables in the estimation: (1) proxies for local R&D capability (the share of manufacturing plants, share of high-tech plants in the manufacturing sector, and average labor productivity in manufacturing); (2) availability of potential partners for R&D collaboration (the number of large manufacturing firms with more than 300 employees, the number of R&D institutes, and the number of universities in the prefecture⁸); and (3) the scale and structure of public expenditures (the number of administrative officers per capita in natural logarithm, the share of industry and commerce expenditures, and the current account⁹).

The variables in Groups (1) and (2) represent the demand factors (proxies for policy needs of local firms). We expect that the propensity of implementing R&D support policy may increase with local firms' policy needs (Hajnal and Trounstein²⁰¹⁰). However, if it is a general policy aimed at catching up with other regions, then we may also expect that policy support may be provided in higher propensity in regions with relatively lower R&D potential (Lanahan and Feldman²⁰¹⁵). The variables in Group (3) indicate the supply factors as the proxies for local authorities' level of administrative services and budget constraints. We hypothesize that these factors affect the probability of local authorities implementing public R&D support programs for local SMEs as economic and institutional factors (Hajnal and Trounstein²⁰¹⁰). We also control for city scale measured as the population size in natural logarithm and the status of the city (the dummy for prefecture capitals)¹⁰. We assume that cities with a large population and higher administrative centrality in the region may be more likely to implement their own R&D support policies as "leaders" and "role models." In the estimation, we use the data before 2009, the median of the start years of the support policies, in order to consider the time-series consistency.

In the next estimations of the determinants of program design, we use the following four dummies as the dependent variables: dummies for (1) the length of subsidy, which takes one if public support exceeds one year and zero otherwise; (2) the high ratio of subsidy, which takes one if the upper limit of subsidy ratio is above 50% and zero otherwise; (3) the flexibility in expenses, which takes one if the subsidy is allowed to cover personnel expenses and zero otherwise; and (4) the generosity in receiving public support, which takes one if the same project is allowed to be simultaneously funded by other public subsidies and zero otherwise. We focus on these dependent variables, since they represent basic conditions of public R&D subsidy and show a large variety across city programs, as we show in Section 3.

We employ probit models again because the dependent variables are dummy variables. For these estimations we use the same independent variables as the first estimation except for business field dummies that are not used in the first estimation. We include them as additional control variables in the estimation models of program designs because they may differ across the target business fields of subsidy programs. In the following subsections we conduct these estimations separately and independently but we will also check possible sample selection bias and the robustness of our estimations.

6.2. Determinants of Program Implementation

First, we estimate the factors of implementing an R&D subsidy program using a probit model. Our research question is which city (or local authority) provides R&D subsidy programs for local firms. Tables 1 and 2 show the basic statistics and correlation matrix of the variables. The final sample is limited to 772 cities because some data was missing due to administrative mergers. Table 3 presents the estimation results on the propensity for implementing local R&D support policies. In this table, we also show the marginal effects, and not the coefficients, of each independent variable.

These estimation results suggest that, even controlling for the size and administrative status of the cities, regional specialization in manufacturing (the share of manufacturing establishments) and active administrative services (number of administrative officers per capita and the share of expenditures for industry and commerce) significantly increase the propensity of implementing R&D support programs. For example, a 1% increase in the number of administrative officers per capita will lead to a 0.216% increase in the propensity of implementing R&D support programs, which suggests a large impact. We also find that the current account has a negative and significant effect on the probability of R&D subsidy programs. As a negative value of current account in this case means budget surplus, this result suggests that the cities with a sound public finance structure are likely to implement R&D support programs.

These findings fully support H1a that the implementation of local R&D support policies depends on supply-side factors of local government, but only partially support H2a on potential local needs (regarding the agglomeration of manufacturing firms) and do not support H3a on potential R&D partners. These results are consistent with those of Lanahan and Feldman (2015), in which state revenue has a positive and significant effect on federal states' propensity to implement their own SBIR subsidy. Overall, these results suggest that supply-side factors (H1a) may be more important than demand-side factors (H2a and H3a) in implementing local R&D policies. In this regard, we may argue that negative effects of demand-side factors (local authorities in the region with weak R&D activity tend to implement these programs for catch-up) offset and thus weaken their positive effects. These results are consistent with those of Lanahan and Feldman (2015), in which state revenue and high-tech employment have positive and significant effects on federal states' propensity to implement their own SBIR subsidy.

(1) This table shows marginal effects instead of coefficients. (2) Level of significance: *** 1%, ** 5%.

Contrary to our expectation, we find that the number of large manufacturing firms in the region negatively affects the probability of public R&D subsidy. This result may suggest that cities in which employment relies on large firms find it less necessary to implement support programs for local SMEs. Regarding control variables, the results suggest that larger cities (measured as population size) have significantly higher propensity to implement their own R&D subsidies. A 1% increase in the population leads to a 0.165% increase in the propensity of policy implementation. However, when controlling for population size, prefecture capitals are not significantly different from other cities with regard to the propensity of policy implementation. This may be because prefecture capitals may be expected to play a leadership role in local policies, but may also be more dependent on prefecture's policies in the sense that they do not need their own policies when a similar policy is implemented by their prefecture. Thus, the positive and negative impact may offset each other.

The above estimation results do not significantly change when the upper bound of subsidy per project is changed from one million to two or three million yen, with an exception for the result on the number of large manufacturing firms. Thus, we may regard these estimation results as robust regarding the amount of subsidy per project. Moreover, the results do not considerably change when we use the number of students or only national universities instead of the total number universities in the prefecture. From these findings, we may cautiously conclude that the supply-side factors (the conditions of public service of each city administration) are relatively important for the decisions of R&D support programs in relation to local SMEs.

6.3. Determinants of Program Design

In the next step, we examine the determinants of the design (scale, contents, conditions and procedures) of local R&D subsidy programs. More specifically, we investigate whether and how the local factors used in the estimation in the previous section may affect program features, such as the length of subsidy, the upper limit of subsidy ratio (up to 50%, two-thirds etc.), whether the subsidy may cover personnel expenses, and whether multiple subsidization by different levels of governments is permitted. We focus on these variables because we find that, according to our survey, the features of R&D subsidy programs by local authorities differ considerably. This may also influence the attractiveness and user-friendliness of these programs. For example, a subsidy program for less than one year would be too short to accomplish any fundamental innovation.

Thus, we use the following four dependent variables: (1) subsidy length (dummy variable of whether the program covers a period longer than one year); (2) subsidy ratio (dummy variable of whether the subsidy's upper limit is above half of the total budget); (3) cost coverage (dummy variable of whether the subsidy can be used for personnel expenses); and (4) the relationship with national and prefectural programs (dummy variable of whether an overlapping subsidy with a national or prefectural program is possible). The value one for these variables mean that local R&D subsidy programs provide favorable conditions for the recipients in that (1) the term is longer than one year, (2) more than a half of project budget can be publicly funded, (3) research and support staff may also be employed, and (4) the same project can also be supported by prefecture or central government, respectively.

In addition to the independent variables previously used, estimation models in this stage include business field dummies. With these new variables, we control for any unobservable differences in program designs across business fields. We hypothesize that, similar to the determinants of program implementation, both demand and supply factors matter for the design of local public R&D subsidy programs (H1b, H2b, and H3b).

In this stage we exclude all cities that did not implement an R&D support policy in 2015. Our sample is therefore limited to 129 cities (including special wards in Tokyo) that conducted at least one R&D support program in 2015. As some cities implemented two or more related policy programs in 2015, in these cases we selected the major program for each city (in terms of total budget size) and excluded others from the sample in order to obtain one-by-one matching between cities and subsidy programs. Table 4 shows basic statistics of this final sample of 120 cities. A correlation matrix of the variables for this sample is provided in Table 5.

Table 4. Basic statistics of cities that implemented R&D subsidy programs in 2015.

In the following estimations, we again employ probit models because all dependent variables are dummy variables. After these basic estimations, we also provide the results of other estimation models (Heckman’s two-step estimations, structural estimation modeling, and bivariate probit models) as robustness checks in the following subsection.

Table6 shows the estimation results of the designs of local R&D subsidy programs. First, regarding subsidy length (dummy for subsidy longer than one year), high-tech ratio, and number of large manufacturing firms have positive and significant effect. Second, the upper limit of subsidy ratio (dummy for upper limit above a half) is positively and significantly affected by manufacturing share, number of large manufacturing firms and universities (in the same prefecture), and the current account of local government. Third, public subsidy may cover personnel expenses in cities where many high-tech firms as well as large manufacturing firms are located. Fourth, multilevel subsidization with prefecture or national government’s subsidy is permitted by cities with a higher ratio of high-tech firms but with lower productivity of manufacturing firms.

These results support H2b and H3b partially, but do not support H1b. It is noteworthy that the factors which significantly affect program design differ considerably across design measures. Yet, almost no supply-side factors have significant effects with expected signs, while either high-tech ratio in manufacturing firms or number of large manufacturing firms (demand-side factors) positively and significantly affects all measures of subsidy program design in favor of recipient firms. In contrast to the results on the implementation of local R&D subsidy programs, we find that as a whole program designs depend on the demand- rather than supply-side factors, but some specific factors affect it, program design may also be biased. The results are shown in Table 7. We find that the inverse Mill's ratio is statistically not significant and that the error terms of the first and second stage estimations are not significantly correlated. We can therefore reject the null hypothesis that the estimation results on program designs are subject to sample selection bias. These results suggest that the determinants of implementing R&D subsidy programs are not related to those of program features, which is consistent with the results shown in Tables 3 and 6.

(1) We show only the estimation results in the second stage. (2) This table shows marginal effects instead of coefficients. (3) Level of significance: *** 1%, ** 5%, * 10%. (4) Robust standard errors of coefficients in italic under marginal effects.

Second, we simultaneously estimated four models of program design in Table 6 using structural equation modeling (SEM). The results are presented in Table 8. We find statistically significant correlations between the error terms between Models 1 and 2, Models 1 and 4, and Models 3 and 4, but do not observe significant changes in the estimated results from those in Table 6. Finally, we conducted bivariate probit estimations with Models 1 and 2, Models 1 and 4, and Models 3 and 4, in order to take correlations between the error terms of estimation models into consideration (Table 9). The estimated results did not change significantly from those in Table 6. The results of these additional estimations suggest that our findings are robust to possible biases.

Regarding control variables, population size, which is highly significant in the implementation of local R&D support programs, has no significant effects on program designs. Larger cities are more likely to implement their own R&D subsidy programs, but program designs do not depend on city size.

6.4. Sample Selection Models and Other Robustness Checks

We conducted some robustness checks in this stage. First we estimated Heckman's sample selection models (two-stage probit models) in order to check sample selection bias in the second stage (determinants of program designs). If the program implementation is not randomly selected, but some specific factors affect it program design may also be biased. The results are shown in Table7. We find that the inverse Mill's ratio is statistically not significant and that the error terms of the first and second stage estimations are not significantly correlated. We can therefore reject the null hypothesis that the estimation results on program designs are subject to sample selection bias. These results suggest that the determinants of implementing R&D subsidy programs are not related to those of program features, which is consistent with the results shown in Tables3and6.

Second, we simultaneously estimated four models of program design in Table6 using structural equation modeling (SEM). The results are presented in Table8. We find statistically significant correlations between the error terms between Models 1 and 2 Models 1 and 4, and Models 3 and 4, but do not observe significant changes in the estimated results from those in Table6. Finally, we conducted bivariate probit estimations with Models 1 and 2, Models 1 and 4, and Models 3 and 4, in order to take correlations between the error terms of estimation models into consideration (Table9). The estimated results did not change significantly from those in Table6. The results of these additional estimations suggest that our findings are robust to possible biases.

7. CONCLUSIONS

For several years, regional innovation systems and multilevel governance of innovation policies have attracted much attention. Local authorities are now expected to play a more active and independent role in regional development, including innovation policies for local SMEs in Japan, where regional and innovation policies have traditionally been strongly centralized. However, despite these new policy trends of regional decentralization, few empirical studies have so far been conducted on innovation policies by local authorities. In this sense, as far as we know, this paper is a pioneering empirical study on this research topic.

This paper paid particular attention to local R&D subsidy policies in Japan and, based on our original survey data on local governments, investigated the factors of implementation and design of local innovation policies. The results of the empirical estimation on the determinants of local R&D support programs show that both demand-side and supply-side factors are important in the decisions of local authorities to implement local R&D support program, but that supply-side factors seem to be more important. Further empirical estimations on the determinants of program design suggest that demand factors, especially the presence of high-tech firms and large firms in the manufacturing sector, are correlated with subsidy designs that are favorable for local recipients. These results as a whole support our hypotheses.

A major limitation of this study is its static nature due to cross-section data. It is not possible to obtain information about the start year of each local R&D support program from the websites. Moreover, we cannot collect information about local R&D support programs that ended before 2015. In the questionnaire survey, we asked for the start year of the current program, but 30% reported that they implemented another R&D support program prior to the current one. In some cases, nobody was able to identify the start year partly because some programs remain live with modifications to titles, targets, and contents. Therefore, it is often difficult to identify when R&D subsidy programs really began. With a more dynamic setting with a panel dataset, in which start years of each program could be clearly identified, we would quantitatively examine the effects of national policy schemes and decisions of neighboring local governments as considered by Lanahan and Feldman(2015).

According to the results of our original survey, in only a few cases, local authorities started R&D subsidy programs because neighboring cities started similar programs. In contrast, however, 23% and 22% of the respondents report that they determined the design of subsidy programs by considering neighboring cities' programs or considering the relationship with national and prefectural government, respectively. Hence, the bandwagon effect in local innovation policies may be more than negligible.

A major academic implication of this study is that we obtained clear empirical evidence for the endogeneity of local innovation policies and the main sources of this endogeneity. Based on our estimation results, it is advised that future empirical studies on the effects of innovation policies are undertaken to consider this endogeneity issue. Moreover, from a practical point of view, the findings of this study may be considered when designing local public policies and the relationship between public policies at different levels.

Major policy implications may also be derived from this study. National government should consider the existing conditions of local economies and authorities in encouraging and evaluating policy initiatives by local authorities. Local authorities should consider local conditions (demand-side factors) more seriously in order to provide original local policies. We hope our paper may encourage empirical studies on the roles and strategies of local authorities in regional innovation systems and the multilevel policy mix in innovation policy.
